

## Exercise 6

### Project Description

**Title:** Object Detection and Image Classification

**Team:** Sascha Stelling and Shivali Dubey.

**Problem Definition:** Object Detection and image classification have various applications, for instance, in self-driving cars to detect and classify pedestrians, motorcycles, trees, bicycles etc; classification of features on Earth such as roads, rivers, agricultural fields etc using satellite images. With the advancements in deep learning, every year, new algorithms/ models keep on outperforming the previous ones, to achieve the best possible accuracies for image classification. One of the most popular dataset used is the ImageNet dataset. In our project we propose to implement the deep learning algorithms based on a few selected studies [1, 2, 3, 5] with the aim to attain the best possible classification accuracy. The classification is represented using bounding box. The bounding box is represented by a 4-D vector storing its centre co-ordinates, width and height [1, 5].

**Dataset:** Tiny ImageNet. Tiny Imagenet has 200 classes. Each class has 500 training images, 50 validation images, and 50 test images.

**Approach:** With such a large dataset, one of the main challenges of classification is diversity of the images. Our model/algorithm must be able to handle fine-grained and specific classes even when they are hard to distinguish. In other words, we need to maximize inter-class variability, while minimize intra-class variability. At the same time, attaining the best possible classification accuracy is always a challenge for any given algorithm. The predictions go wrong when you have too many false positives and false negatives.

#### Architecture:

1. **Convolution:** The main purpose of using multiple convolution layers is feature extraction. We use SIFT descriptors to detect and describe the local features of the images. To classify feature more accurately we make use of densely sampled SIFT, Extended Opponent SIFT and RGB-SIFT detector as described in [1]. We use Parametric ReLU (PreLU) for activation of neuron instead of ReLU because it improves model fitting with nearly zero computational cost and little overfitting risk [2]. Also, PreLU (and also ReLU) brings non-linearity into the system which allows learning complex functions. The weight initialization can be performed using Xavier's initialization [2]. Further, the weight optimization is also controlled by PreLU.
2. **Downsampling:** Though the activation function passes only relevant pixels to the next layer, the array could still be big. To reduce the size of the array, we downsample it using an algorithm called max pooling.
3. **Fully-connected Neural Network:** We construct the last layer as fully connected neural network with hidden layer and logistic regression/Euclidean Loss, and set all feature maps produced from previous layers as inputs. Softmax logistic regression can be used to represent categorical distribution i.e. probability distribution over different outcomes.

4. **Backpropagation:** We use gradient descent method for optimization algorithm which is thus used for learning and training.

**Reducing Overfitting:** As studied in previous research works (Imagenet class), we perform data augmentation and dropout to reduce overfitting. Data augmentation refers to artificially enlarging image size using augmentation. Dropout refers to dropping out the output of each hidden neuron with probability 0.5 and less, such that the respective neuron can't participate in backpropagation [5].

**Training:** The image is first cropped representing an object part or a small object. The training is carried out by optimising the multinomial Euclidian loss (for bounding box representation, otherwise regression is more common) objective function using mini-batch gradient-descent (based on back-propagation) [3,4,5].

**Testing:** At test time, we have a trained dataset and an input image. The fully connected layers are converted to convolutional layers resulting into a Fully Convolutional (FC) network. During training, the images are cropped, however during testing the FC network is applied on the entire image. The result is a bounding box location prediction [3,5].

Note: We could also train our dataset by optimising the multinomial logistic regression objective function. In this case, the testing would result in a class score map with the number of channels equal to the number of classes [4,5].

**Results and Evaluation:** We expect our output images to be classified and represented with box bounded objects. The results can be quantitatively evaluated by calculating the top 1 and top 5 test set error rates as done in previous studied [1,2,3,5]. The qualitative evaluation can be performed by selecting 5 most probable class for a given object in an image and computing their probabilities.

#### **Work division:**

Sascha Stelling: Convolution filters, training of dataset (feed forward), testing (result from multinomial logistic regression), Downsampling and fully connected neural network.

Shivali: Defining PreLU function, training of datasets (backpropagation), testing (result from Euclidian loss objective function), Reducing overfitting.
